Abstract
A peripheral ossifying fibroma (POF) is a benign fibro-osseous lesion of a reactive rather than a neoplastic nature, whose pathogenesis is uncertain. Repeated clinic-pathological studies on the POF have not addressed the pediatric population in specific detail. This case is probably the few discovered which demonstrates POF in a pediatric patient.

Key words: Gingiva, peripheral ossifying fibroma, surgical excision

Introduction
Many types of localized reactive lesions may occur on the gingiva including focal fibrous hyperplasia, pyogenic granuloma, peripheral giant cell granuloma and peripheral ossifying fibroma (POF). POF is typically a solitary, slow growing, nodular mass, which may be either pedunculated or sessile. Solitary gingival enlargements in children are a relatively common finding. Usually, these enlargements are a response to local irritation. POF is one such reactive lesion.

POF is often composed of a cellular fibroblastic connective – tissue stroma associated with the formation of randomly dispersed foci of a mineralized product consisting of either bone, cementum like tissue or dystrophic calcifications. This may be the reason why in the literature, this pathologic lesion sometimes has been described as an ossifying fibroid epulis, a peripheral fibroma with calcification or a calcifying granuloma. However, in 1982, Gardener recommended that the only term used to describe this lesion should be POF.

POF usually measures < 1.5 cm in diameter, but patients with a lesion of 6 cm and 9 cm have also been reported. Etiology and pathogenesis of POF remains unknown. Some investigators consider it as a neoplastic process, whereas others consider it as a reactive process. In either case, the lesion is thought to arise from cells in the periodontal ligament. Trauma or local irritants such as dental plaque, calculus, micro-organisms, masticatory forces and poor quality restorations have been implicated in etiology of POF.

Case Report
A 13-year-old male patient reported to the Department of Pedodontics and Preventive Dentistry complaining of soft tissue growth in the upper front teeth region since 1 year. The swelling was of smaller than peanut size when he noticed for the first time and gradually increased to reach the present size. There was no history of trauma to the same region. The medical status was non-contributory, and family history was not significant. On intra-oral examination, a soft tissue swelling was found between maxillary central incisors attached to the gingiva. The growth was firm in consistency, pedunculated, solitary and pinkish in color with no associated pain [Figure 1]. It measured about 7 mm × 8 mm diameter and tends to bleed while brushing. Periapical radiographic examination revealed both central incisors with normal periodontal ligament space and periradicular architecture [Figure 2]. The case was provisionally diagnosed as irritation fibroma, and surgical excision of the same
lesion was planned. After obtaining signed informed consent, the growth was surgically excised under local anesthesia. Following excision profuse bleeding was noticed, and this was controlled using cotton pack for few minutes [Figure 3]. The excised specimen was sent for histopathological examination and finally diagnosed as POF based on both clinical and histological features [Figure 4]. Patient was kept under observation and followed up after 3 months with no recurrence in the lesion [Figure 5].

Discussion
Intraoral ossifying fibromas have been described in the literature since 1940s. Many names have been given to similar lesions such as epulis, peripheral fibroma with calcification, POFs, calcifying fibroblastic granuloma, peripheral cementifying fibroma, peripheral fibroma with cemento-genesis and peripheral cement-ossifying fibroma.[4] All the terminologies are appropriate for this tumor as they may contain a variety of calcified material. When bone predominates in the lesion, the term “ossifying” is used. The term “cementifying” has been assigned when the curvilinear, trabecular or spherical calcifications are encountered. However, when both cementum and bone-like tissues are observed the lesions are then referred to as cement-ossifying fibroma.[1]

POF represents a common gingival growth, usually arising from the interdental papilla and representing up to 2% of all

lesions that are biopsied. In pediatric patient studies, the incidence of POFs in biopsied lesions ranged from 1% to 2%. The main etiological factors of POF are trauma and chronic irritation, particularly from sub-gingival plaque and calculus. Furthermore, trauma or local irritants such as ill-fitting dental appliances and poor quality dental restorations play a significant role in the etiology and pathogenesis. Eversole et al. stated that the constant irritation present during exfoliation of deciduous teeth and eruption of the permanent teeth may also result in an increased incidence of reactive lesions, which originate from the periodontal ligament. This hypothesis is based on the fact that POFs arise exclusively on the gingiva, the subsequent proximity of the gingiva to the periodontal ligament and the inverse co-relation between age distribution of patients presenting with the POFs and the number of missing teeth with associated periodontal ligament [Table 1]. Clinically, POFs present as exophytic, smooth surfaced pink or red nodular mass that is sessile or is less frequently seen on a pedicle.

Ossifying fibromas occur from craniofacial bones and is generally categorized into two types, central and POFs. The central type arises from the endosteum or the periodontal ligament adjacent to the root apex and expands from the medullary cavity of the bone. On the other hand, the peripheral type shows a contiguous relationship with the periodontal ligament, occurring solely on the soft tissue. POF is not peripheral counterpart of the central ossifying fibroma. Inflammatory hyperplasia originating in the superficial periodontal ligament is considered to be a factor in the histogenesis of POF.

Ossifying fibromas may occur at any age, but are more common in young adults. A variant of ossifying fibroma, juvenile (aggressive) ossifying fibroma, has been described in children and young adults who are younger than 15 years of age. While POF occurrence is uncommon in the neonate, it is not difficult to rationalize that the active growth of alveolar bone in the neonatal jaw, when stimulated by removal of neonatal tooth, might respond with an exuberant periosteal response and form a reactive lesion. Females are more commonly affected than males. High female predilection, a rare occurrence in the first decade, and decline in incidence after age 30 suggest that the hormonal influence maybe a lesional growth factor. According to Buchner and Hansen, POFs occurred 60% of the time in maxilla and 40% in the mandible, and 54% occurred in the incisor/cuspid region.

Histologically, these lesions are fibro-osseous in nature. They are composed of cellular fibrous tissue with areas of fibro-vascular tissue that often contain an inflammatory component with abundant plasma cells. Ossification is usually seen in the cellular zone and shows a considerable variation both quantitatively and qualitatively. From small rounded calcified deposits to large trabecular bone areas surrounded by osteoblasts may be observed. The predominant cell of this lesion is a bland spindle cell. Mitotic figures are rare. Admixed in the fibrous background are irregularly shaped osseous. The histopathological hematoxylin and eosin stained section of lesion revealed a well-circumscribed, encapsulated mass; the capsule was fibrous and thinned out at places. The subcapsular area comprised interconnected bony trabeculae encasing plump osteocytes with most of the trabeculae exhibiting osteoblastic rimming. Concentric lamellated and spherical ossicles were seen with a basophilic center and peripheral eosinophilic mass. The fibrous tissue is of varying cellularity with few chronic inflammatory cells.

The recommended treatment of POF is a local surgical excision that extends to include the periosteum with submission for histopathological examination. Local resection is done with peripheral and deep margins including both the periodontal ligament and the affected periosteal component. In addition, elimination of local etiological factors such as plaque and tartar is required. Rate of recurrence may re-occur incomplete excision or repeated injury.

POF: Peripheral ossifying fibroma

**Conclusion**

A POF is a slowly progressing lesion, the growth of which is generally limited. Many cases will progress for long periods
Peripheral ossifying fibroma with literature review

before the patient seeks treatment, because of lack of symptoms associated with it. The treatment of these focal reactive overgrowths is complete excision and most importantly, regular follow-up should be established to check for any recurrence.
